

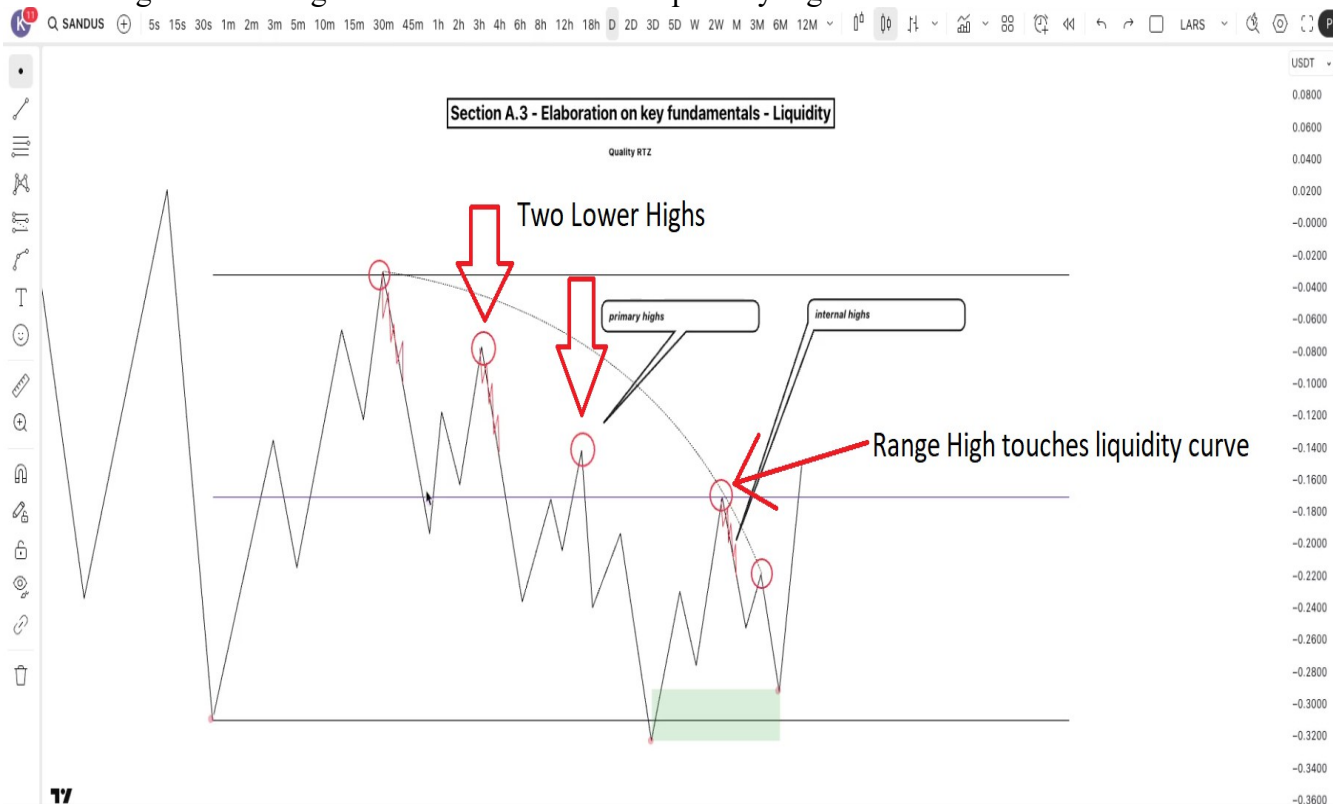
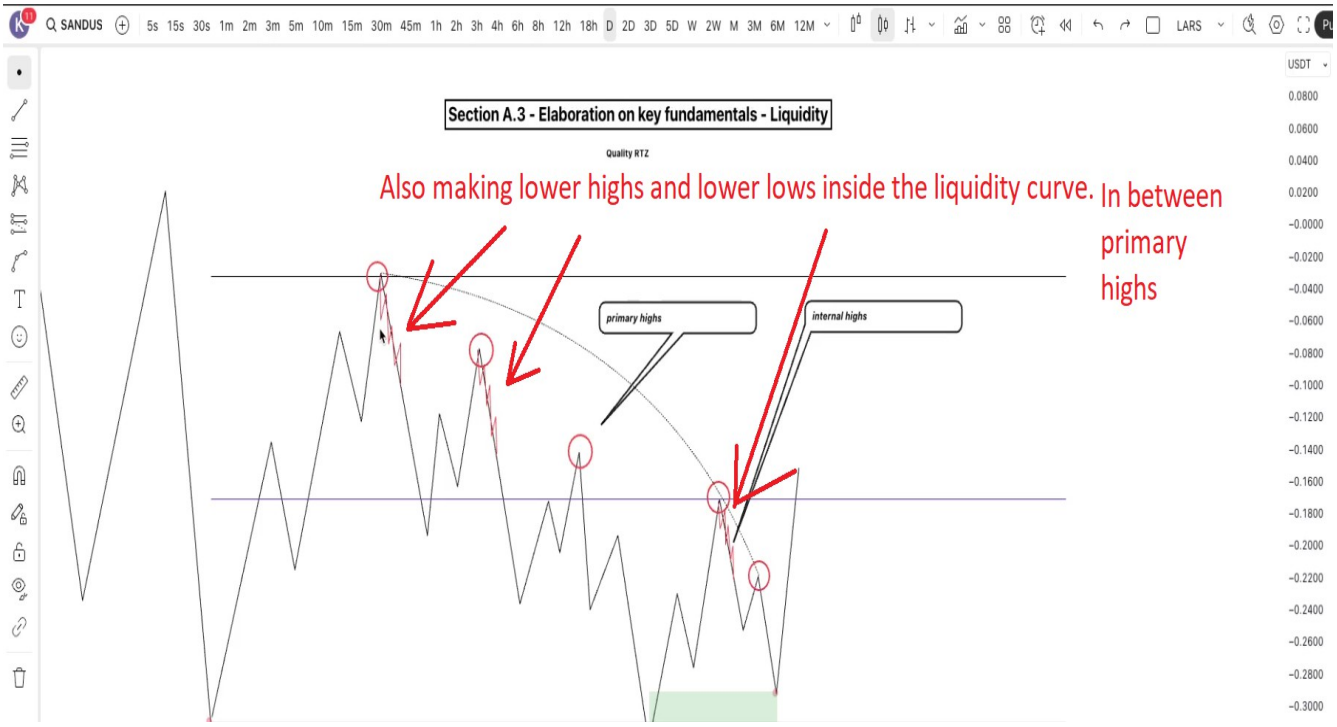
Day time frame -

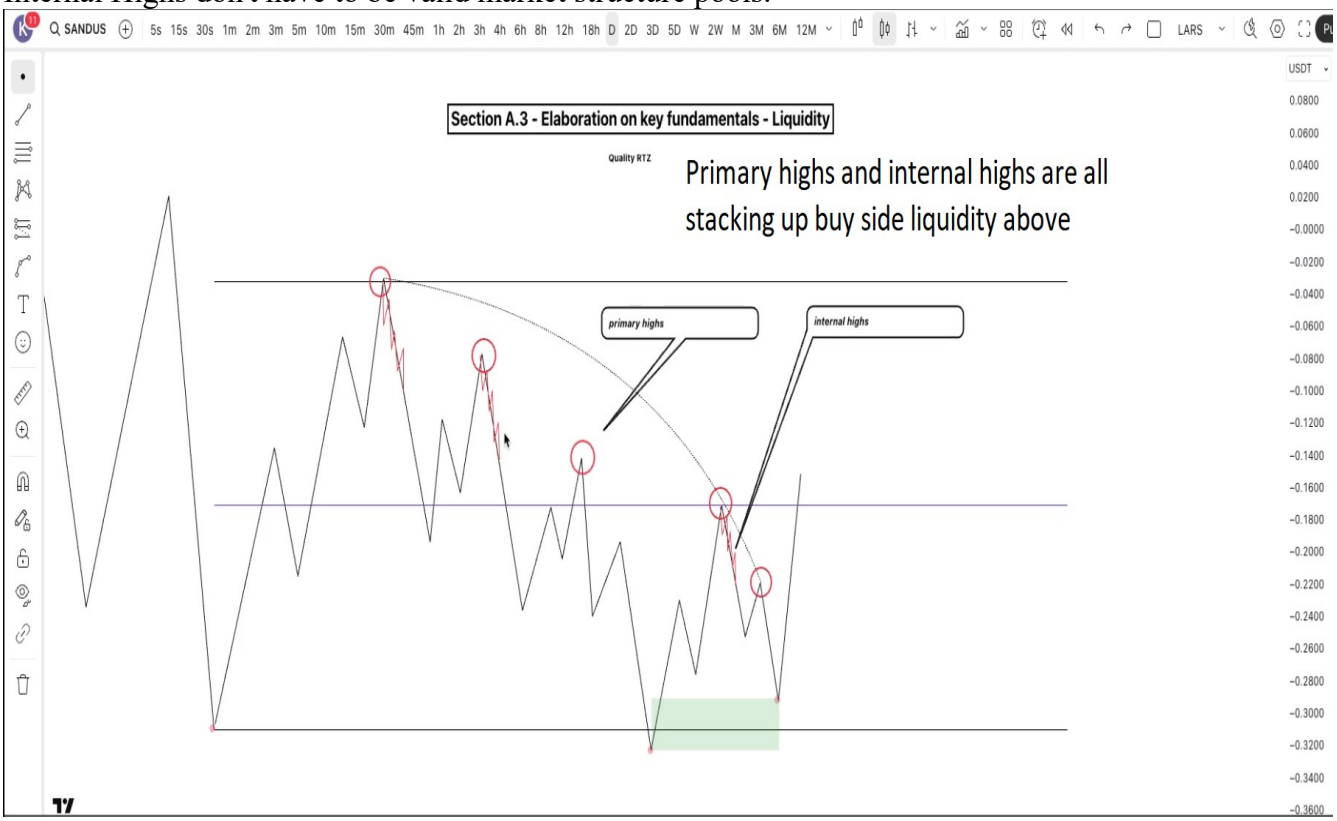
The points all don't need to connect. We need just a few points to have a proper liquidity curve. Visible pivot points are our primary highs. Typically you want each primary high to be a lower one to the previous one. We would like to have the supply get mitigated on the 2nd primary high. So you don't have any supply that is protecting that price from coming to that high in case of an accumulation model.

Internal highs are our high creations in between our primary highs.

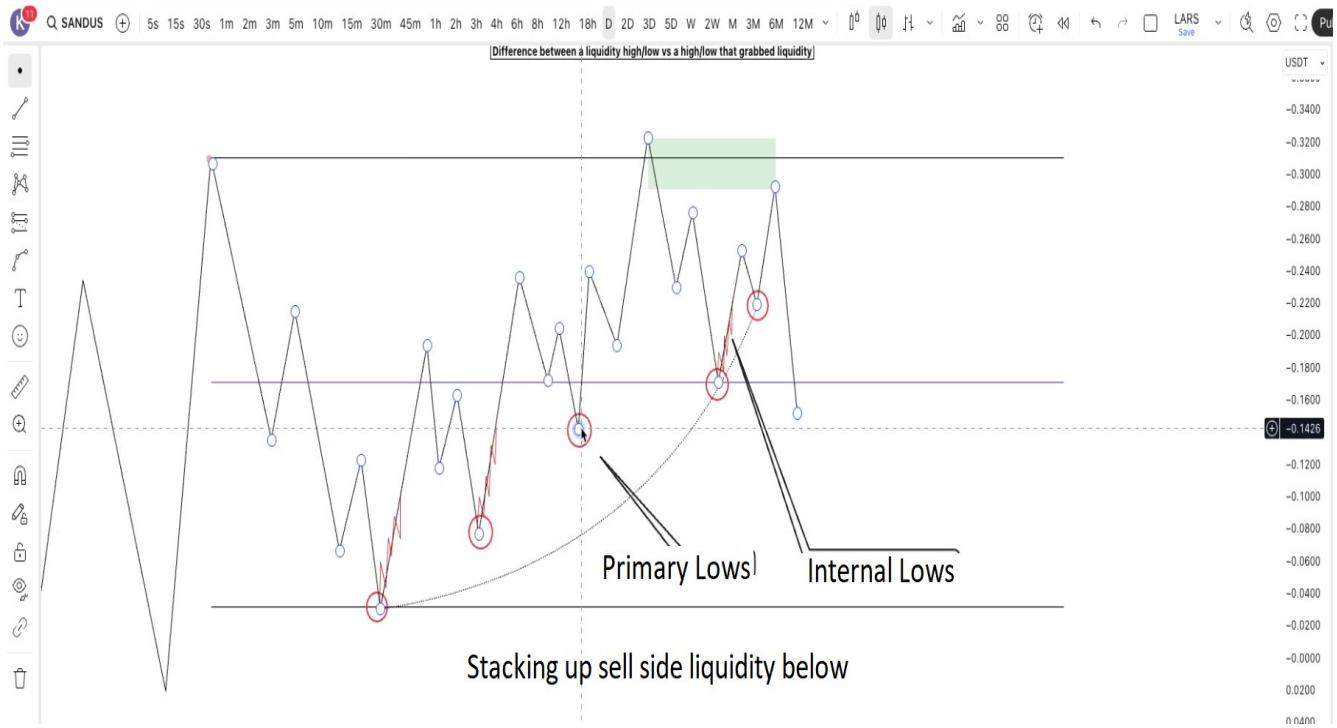




Internal Highs don't have to be valid market structure pools.



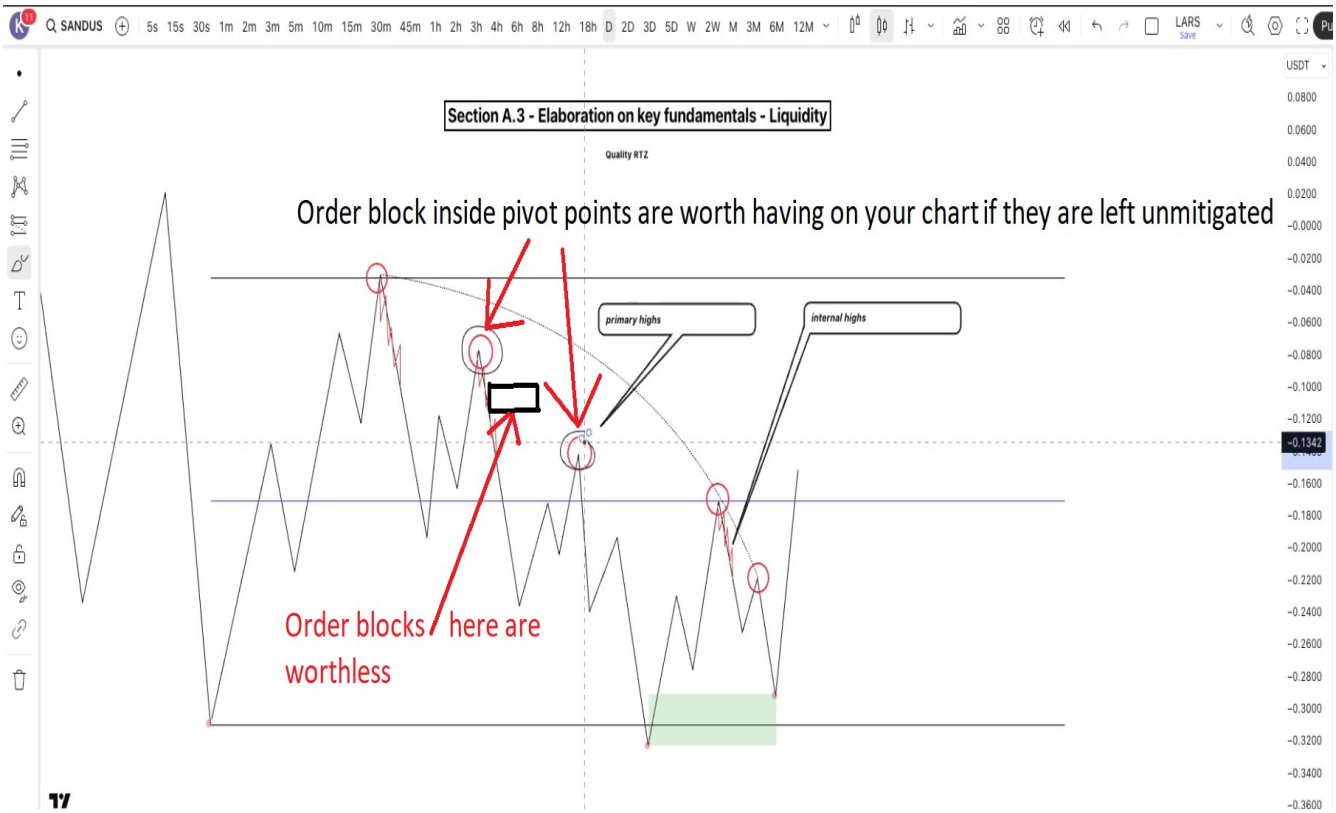
Above is just the opposite of a distribution model. If it were a distribution model it would look like this if you inverse the chart:

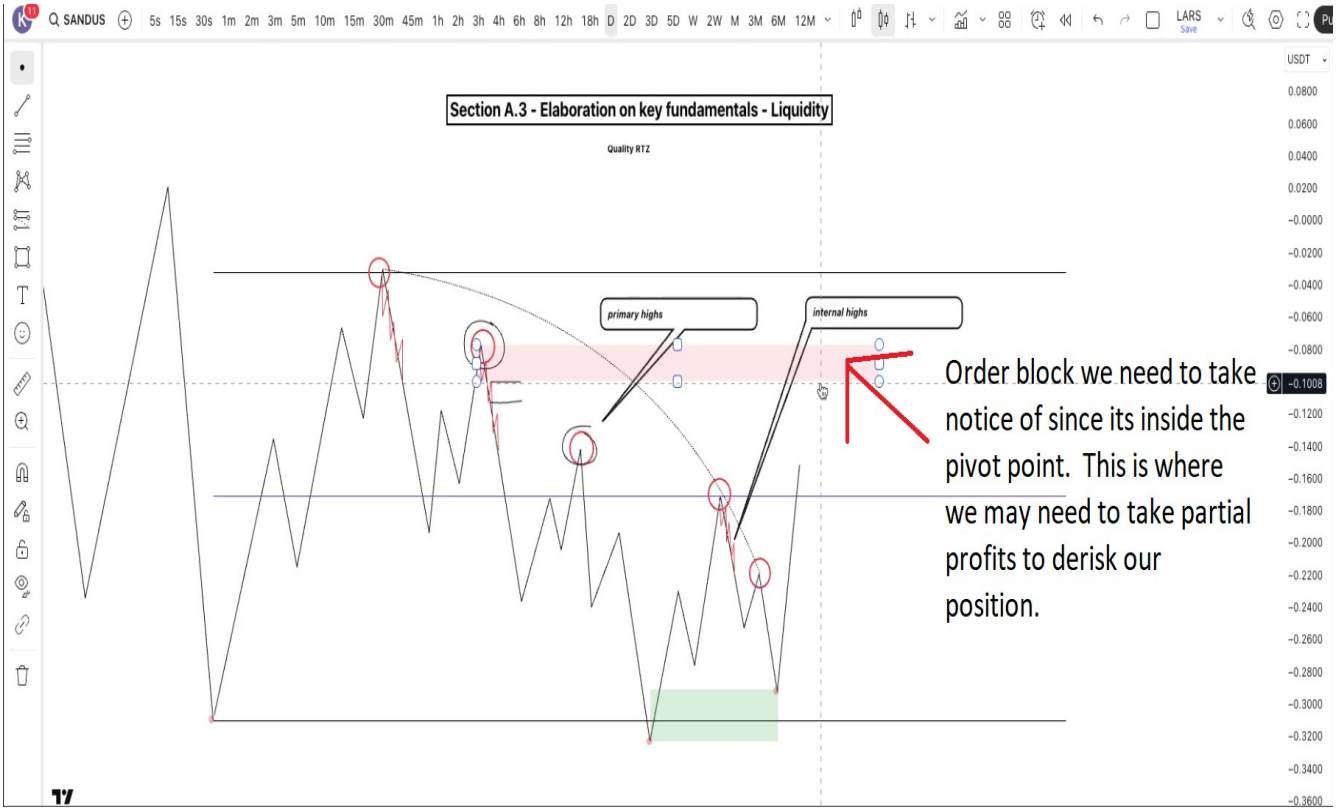


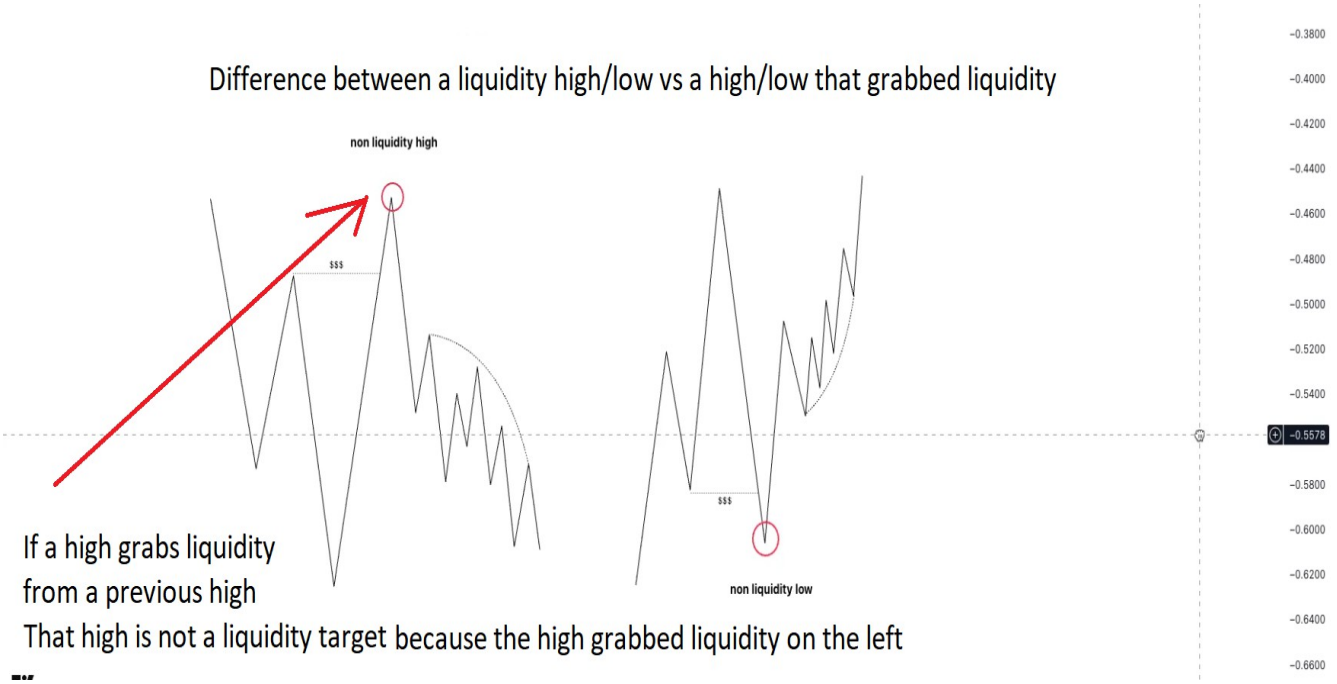
Lower lows inside primary lows stacking up indicating almost nothing other than sell side liquidity

below. Making it very easy to confirm a rotation back down.

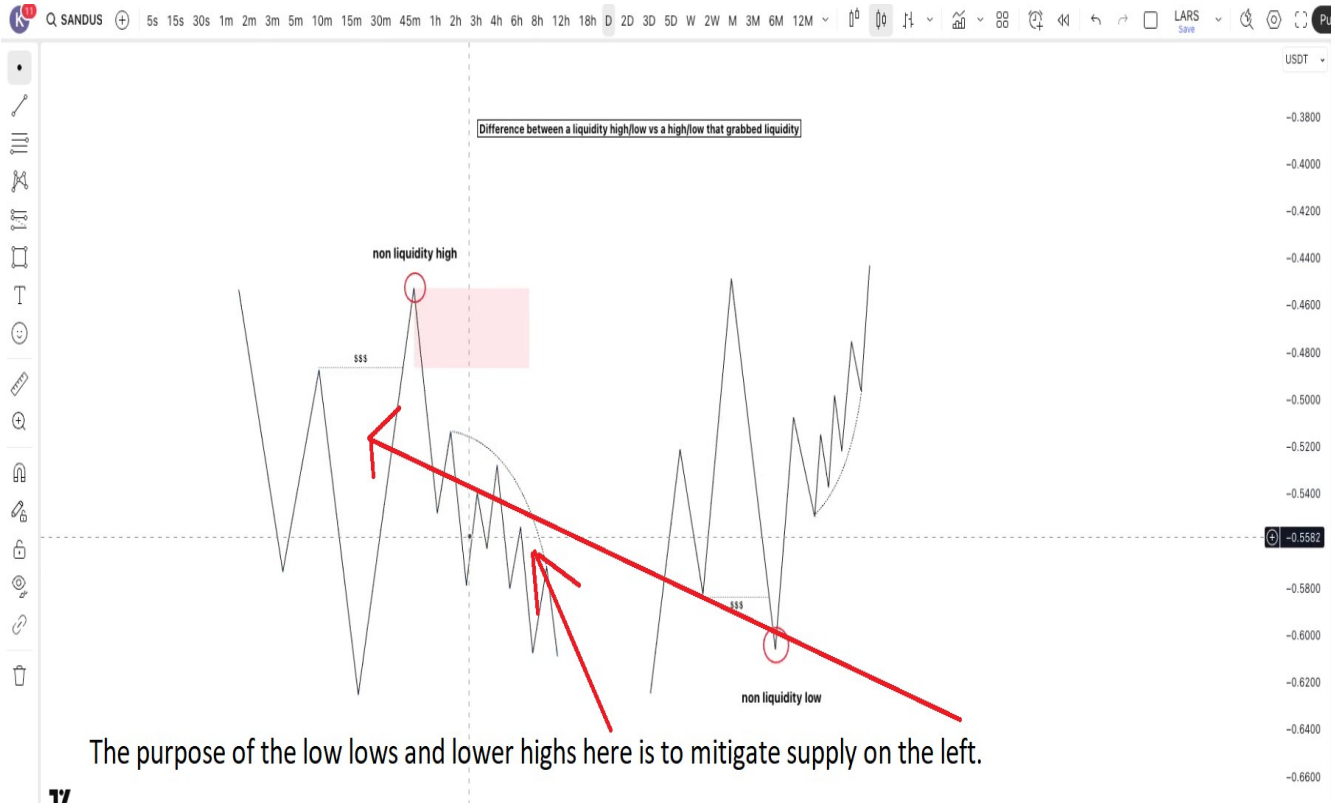
A single OBIF(Order Block with Inefficiency) in the middle of our liquidity curve does not invalidate an entire return to zone. If the order block is located in between the internal highs we can completely ignore it because its worthless. If its located inside a pivot point of our primary highs we need to put it on the chart and we need to be aware of it and it is a POI that price could reject from but if everything around that order block is developing in a high probability fashion the rejection from the block will probably be just temporary and eventually making its way to the technical target.



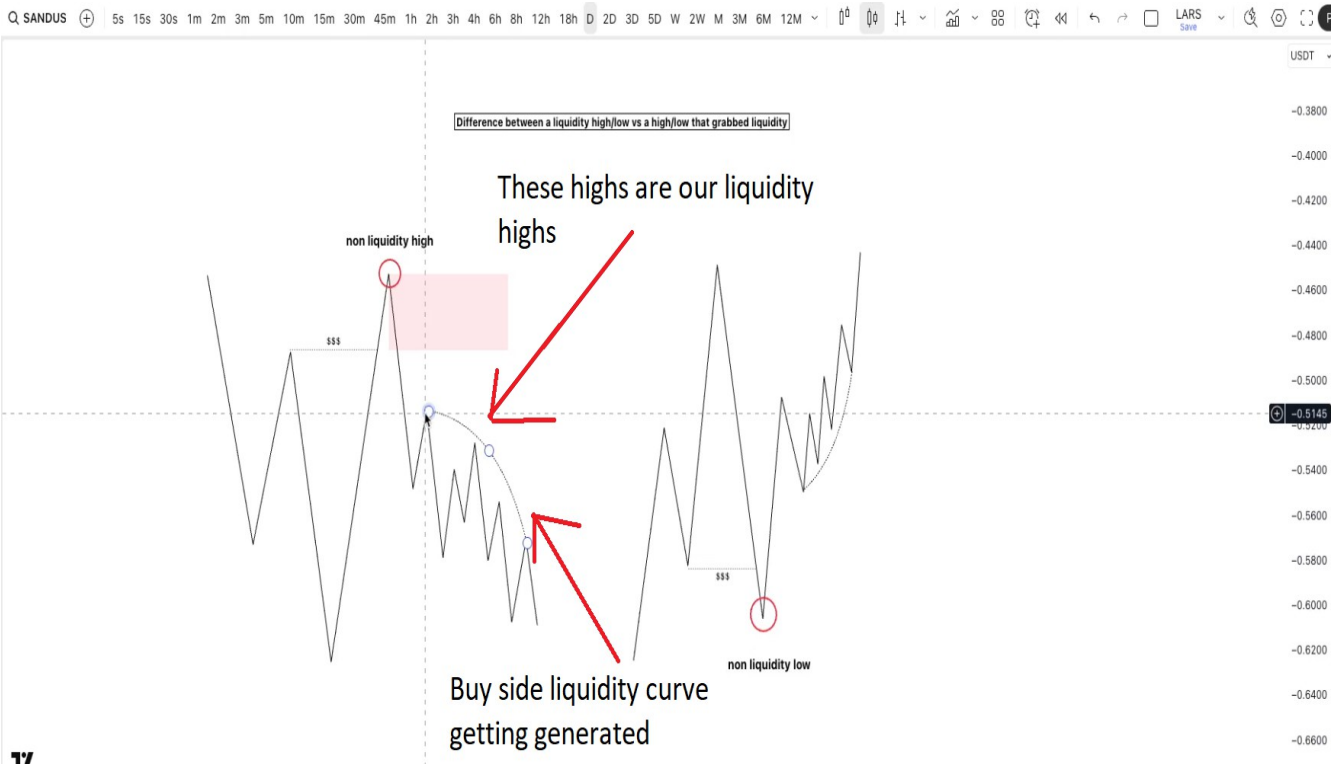




this typically happens because short sellers place their stop loss just above the previous high. If this is the case retail isn't shorting actual pivot points because it grabbed liquidity on the left. Often you will see a more aggressive expansion towards the downside from it. That non liquidity high should not be apart of your plan for return to zone.

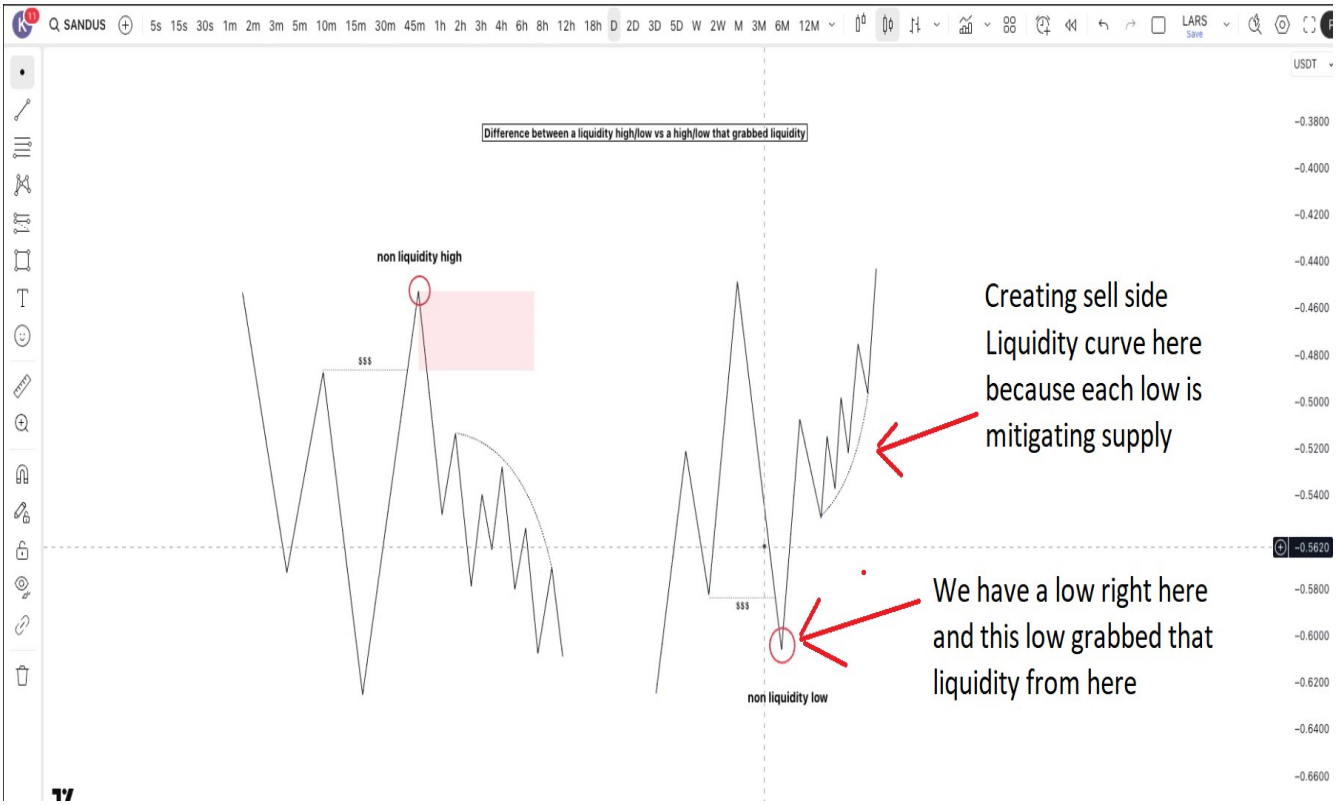


SANDUS
Difference between a liquidity high/low vs a high/low that grabbed liquidity
non liquidity high
$$$
$$$
non liquidity low
The purpose of the low lows and lower highs here is to mitigate supply on the left.



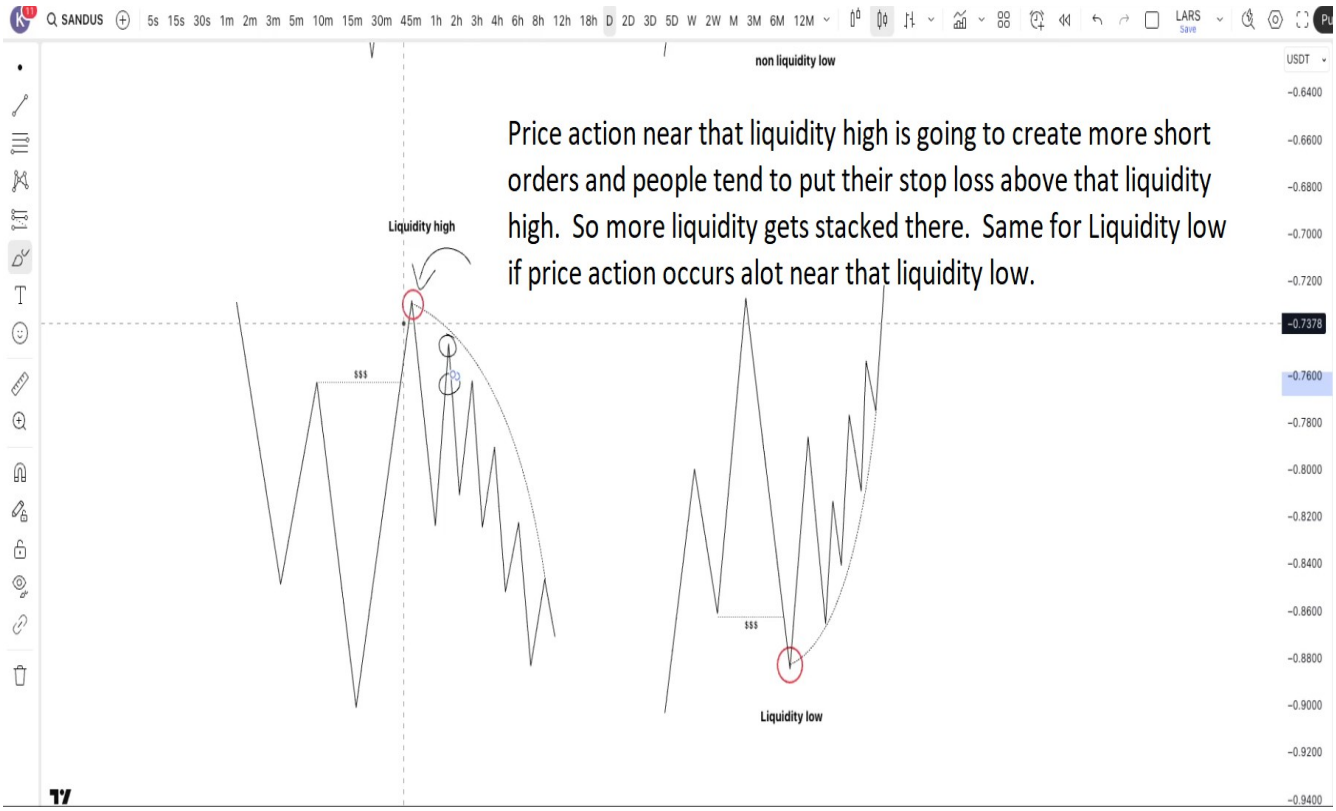
SANDUS
Difference between a liquidity high/low vs a high/low that grabbed liquidity
These highs are our liquidity highs
non liquidity high
$$$
$$$
non liquidity low
Buy side liquidity curve getting generated

The exact same thing happens from a liquidity low perspective.

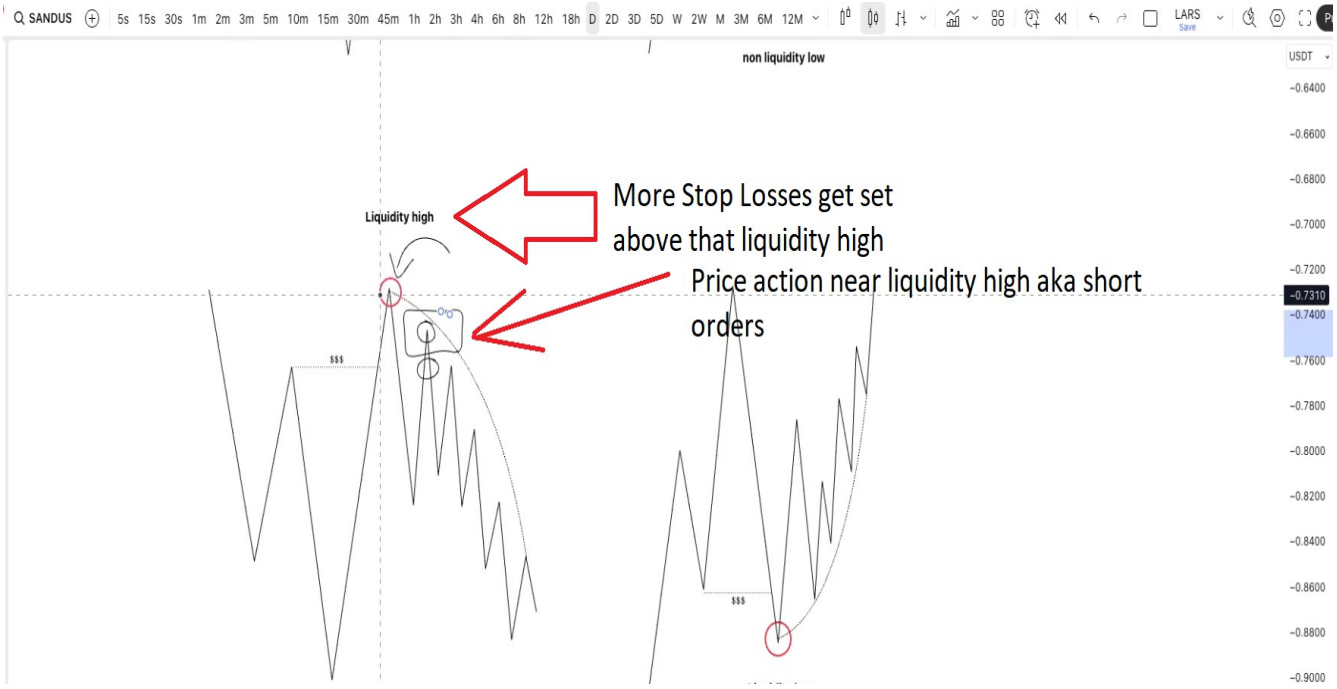


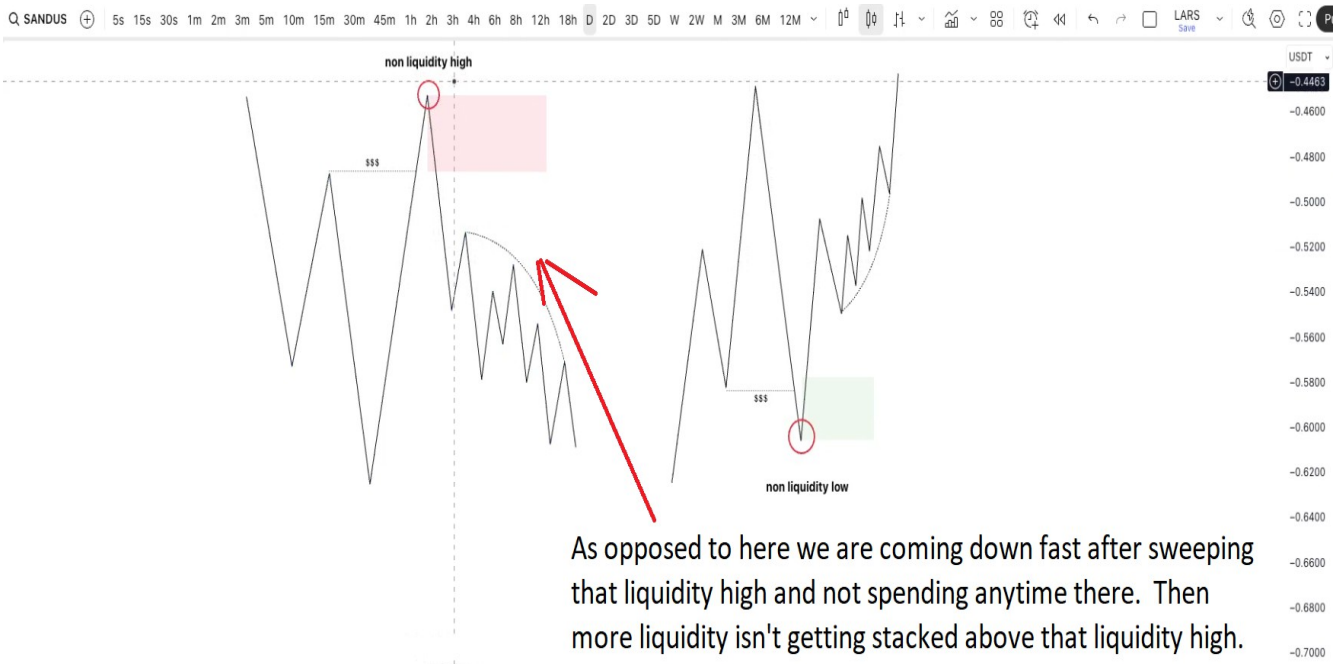
So a non high liquidity or a non low liquidity move is very important to understand because it will prevent you from using the incorrect 3rd tap Point of Interests for looking at potential model 2 TCT models.

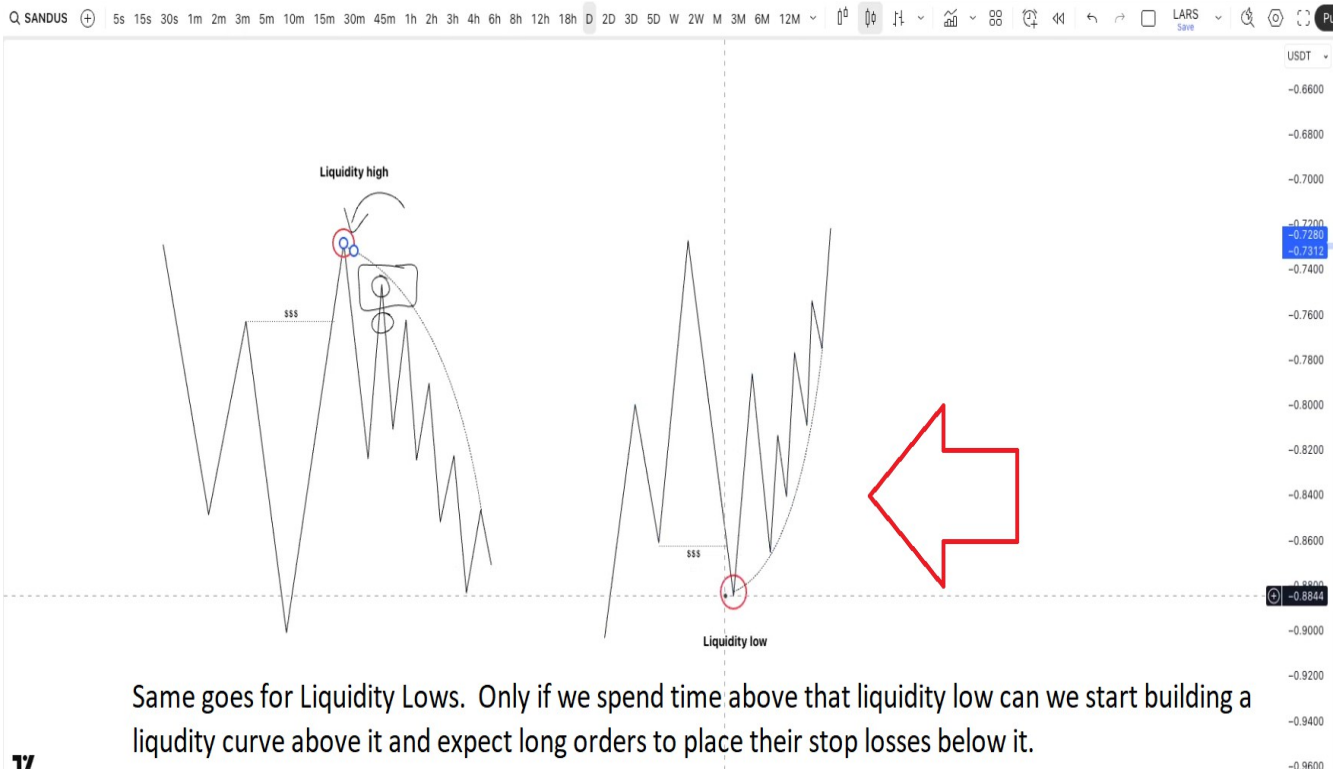
Exception to that is liquidity gets swept than immediately starts creating price action near that high or near by the low. Not leaving behind any sort of demand or inefficiency.



If price is spending time nearby that liquidity high than that high becomes apart of your liquidity curve.







This is important to our model 2 POIs in our TCT schematics.
